# The following two functions are copies form GenABEL package by Y. Aulchenko,
# which are very useful for transformations, but not available from CRAN or
# Bioconductor for modern R. We include them as part of the script.
# The ztransform function standardizes the residuals of a linear model,
# while the rntransform function performs a rank-based inverse normal transformation
# on the dependent variable.
# Load the R script from GitHub

# Simulate example data
set.seed(42)
n <- 1000
genotype <- sample(c("0", "1", "2"), size = n, replace = TRUE, prob = c(0.25, 0.5, 0.25))
age<-rpois(n, 50)
dependent <- ifelse(genotype == "0", 1, ifelse(genotype == "1", 2, 3))
dependent <- dependent + 100*rexp(n, rate=10) + rnorm(n,10,1) + age/10

# Create a data frame
data <- data.frame(genotype = as.numeric(genotype), dependent = dependent, age=age)

# Inspect residuals for normality
model_original <- lm(dependent ~ genotype + age, data = data)
residuals_original <- residuals(model_original)

# Apply a transformation (natural log transformation)
data$dependent_transformed <- log(data$dependent)
model_transformed <- lm(dependent_transformed ~ genotype + age, data = data)
residuals_transformed <- residuals(model_transformed)

# Set common axis limits based on the range of all residuals
common_limits <- range(c(residuals_original, residuals_transformed))

# Reminder of interpretation of qq plot: If the data is normally distributed,
# the points in the Q-Q plot should fall approximately along a straight line.
# If the data is not normally distributed, the points will deviate from the straight line.
```

```r
#example
par(mfrow = c(1, 1))
normal_data <- rnorm(1000)
qqnorm(normal_data,main="Q-Q Plot (Normal Data)")
abline(0,1)
qqline(normal_data, col = "lightblue")
```

```r
# Purpose of the Fitted vs. Residuals Plot:
# Assess Linearity:
# This plot helps determine if the relationship between predictors and the dependent
# variable is linear. Ideally, the residuals should scatter randomly around zero across
# the range of fitted values. If you see patterns (e.g., curves), it may indicate
# non-linearity, suggesting the need for a transformation of the dependent variable
# or predictors.

# Detect Heteroscedasticity:
# Unequal variance (heteroscedasticity) appears as a funnel shape or clustering in
# the plot. Such patterns suggest that the variance of the errors changes with the
# fitted values, which violates a key assumption of linear regression.
#Transformations can address this issue.

# Identify Outliers or Influential Points:
# Residuals that deviate substantially from the zero line or clusters of outliers
# in specific regions of the plot can indicate problems with certain data points.
# RINT or similar transformations can help mitigate their impact by reducing the
```

```r
# influence of extreme values.

# Diagnose Model Fit:
# If the residuals show clear systematic trends, the model is likely mis-specified
# (e.g., missing interactions or non-linear relationships).

# Connection to Transformations:
# If the plot exhibits patterns or non-random residuals, this signals a need for
#corrective measures such as transformations. For example:

# A log transformation can stabilize variance and linearize relationships.
# A RINT transformation focuses on normalizing residuals and is especially
# helpful when extreme values are a concern.

# Let's look at the residuals of the original and transformed models:
# Here, the diagonal is in black, and the qqline is in light blue.

```r
# Interpret the beta coefficients
# The beta coefficient for genotype=1 is the expected difference in
# the dependent variable between genotype=1 and genotype=0, holding
# all other variables constant.
# When the dependent variable is log-transformed (log(y)), the beta
# coefficient represents the expected change in the logarithm of the
# dependent variable (log(y)) per unit change in the predictor variable
# (e.g., genotype levels 0,1,2).
# To interpret the beta coefficient in terms of the original (unlogged)
# dependent variable, you can exponentiate it using exp(beta).

# The resulting value gives the multiplicative effect of the predictor
# on the dependent variable. For example:
# If exp(beta) > 1, the predictor increases the dependent variable
# by a factor of exp(beta).
# If exp(beta) < 1, the predictor decreases the dependent variable
# by a factor of exp(beta).
# If exp(beta) = 1, the predictor has no effect on the dependent variable.
# After transformation, the beta coefficient reflects relative changes
# instead of absolute changes in the dependent variable.

# Suppose the beta coefficient for a genotype in the transformed model is
# 0.05023:

# Log Scale: For each unit change in the predictor (genotype), the log of
# the dependent variable increases by 0.05023.
# Exponentiated Scale:

exp(model_transformed$coefficients[[2]])
```

```
## [1] 1.042429
```

```r
# Indicating that the dependent variable increases by approximately 5.1%
# per unit change in the predictor.
# By transforming back to the original scale, you make the interpretation
# more intuitive and relevant to the practical context.

# Evaluate another type of transformation, the rank-based inverse normal
# transformation (RINT) The RINT is a non-parametric transformation that
# converts the dependent variable into a standard normal distribution.
# The RINT maps the ranked values of the dependent variable onto a standard
# normal distribution, effectively normalizing the variable while preserving
# its rank order. This transformation is useful when the residuals of the
# model are not normally distributed, even after applying other transformations.

```r
# Since RINT normalizes the dependent variable, the beta coefficient reflects
# the standardized effect size. It tells you how much the dependent variable
# (on the normalized scale) changes per unit change in the predictor.
# The values of the beta coefficients cannot be directly translated back to
# the original scale of the dependent variable. They are relative measures
# indicating the direction and magnitude of association within the transformed
# (ranked) scale. RINT reduces the influence of outliers and emphasizes rank
# order rather than raw values. Therefore, the beta coefficient is less sensitive
# to extreme values and primarily describes the overall trend or relationship.

model_rint$coefficients[[2]]
```

```
## [1] 0.1786369

```

```
# In Summary
# If the residuals in a linear model do not meet the assumption of normality,
# it can lead to various consequences.

# Inference Issues:
# P-values and Confidence Intervals: Non-normal residuals can make the
# standard errors unreliable, leading to inaccurate p-values and confidence
# intervals for the regression coefficients.

# Type I/II Errors: Increased risk of falsely rejecting the null hypothesis
# (Type I error) or failing to detect a true effect (Type II error).

# Violation of Assumptions:
# While the normality of residuals is not required for unbiased coefficient
# estimation, it is critical for valid hypothesis testing and for relying on
# outputs such as t-tests and F-tests.

# Loss of Predictive Power:
# Non-normal residuals may indicate issues like heteroscedasticity or
# non-linearity, which can reduce the model's predictive accuracy.

# Underestimation of Extreme Values:
# Non-normal residuals, especially when skewed, can result in poor
# predictions for extreme observations (outliers) in the dependent variable.

# Inefficient Parameter Estimation:
```

```r
# Although linear regression is robust to slight deviations from normality,
# severe non-normality can lead to inefficient parameter estimates,
# particularly if the sample size is small.

# To address these issues, you can apply transformations to the dependent
# variable to improve the normality of residuals! The choice of transformation
# depends on the distribution of the dependent variable and the nature of the
# relationship with the predictor variables.

# Using the fitted vs. residuals plot, Q-Q plot, and Shapiro-Wilk test, you
# can assess the normality of residuals and determine whether a transformation
# is necessary.
```
